L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Magneto-visual-inertial Dead-reckoning: Improving Estimation Consistency by Invariance

David Caruso\textsuperscript{1,2}, Alexandre Eudes\textsuperscript{2}, Martial Sanfourche\textsuperscript{2}, David Vissière\textsuperscript{1} and Guy Le Besnerais\textsuperscript{2}

Abstract—Tractable algorithms used for 6DOF visual-inertial odometry have decades-long history of estimation consistency issues. Those arise in particular in two well-studied filters: namely the EKF-SLAM and MSCKF. Recently, strong theoretical works linked the error-state of these filters with their consistency properties; these results led to the synthesis of far more consistent filters. In previous works, we have shown that using similar filter for the fusion of magneto-inertial sensors with optical ones improved classical visual-inertial navigation systems. The consistency of those novel magneto-visual-inertial filters were, however, not addressed until now. This work does. We apply invariance theory findings to the specific case of magneto-inertial odometry and magneto-visual-inertial odometry for the synthesis of a filter with interesting consistency properties. We describe thoroughly such an invariant filter, implement it and conduct experiments on carefully captured data from real sensor. By comparing the results of non-invariant, observability-constrained and invariant versions of the filter, we find that the invariant version (i) shows an error estimate that is consistent with observability of the system, (ii) is applicable in case of unknown heading at initialization, (iii) improves long-term behavior of the filter and (iv) exhibits a lower normalized estimation error. We experiment on challenging scenarios for regular visual-inertial pedestrian navigation systems.

I. INTRODUCTION

We address here the problem of an embedded device position and orientation estimation. The goal is to estimate these quantities with minimum drift with power efficiency and robustness with respect to the various type of motion. We also target an accurate estimation of the uncertainty of these quantities. In one hand, Visual-Inertial Odometry (VIO) has become a fundamental technology for positioning in spatial computing applications such as augmented or virtual reality. In the other hand, Magneto-Inertial Dead-Reckoning (MI-DR) uses the local magnetic perturbations for correcting accelerometers integration drift and recently showed dramatic performance improvement [1]. As failure modes of MI-DR and VIO are disjoint, it was shown that a fused Magneto-Visual-Inertial Navigation System (MVINS) estimator was more robust than either VIO and MI-DR [2, 3]. These latter references use an algorithm based on the Multi-State Constraint Filter (MSCKF) [4] adapted for MVINS problem that we will name here Magneto-Inertial Multi-State Constraint Filter (MI-MSCKF). It is well-known that, in the context of VIO, the MSCKF applied without extra care is not consistent: the state errors are not well represented by the estimated covariance [5]. In this extent, there is no reason why the MI-MSCKF algorithm presented in [3] would be free from the same flaws than its inspirator.

This paper shows that these inconsistencies are significant issues for MVINS, and address them by leveraging the link between the filter’s error-state definition and its consistency property. We base our work on theory developed in [6], that was already recently applied to VIO [7]. The contributions of this paper are (i) the description of a Lie group-based parametrization for the MVINS model inspired by invariant theory of [6] (ii) the proof that a MSCKF-like filter based on this parametrization has consistency properties (we use here the unobservable stochastic transformation of [7] with some corrections on their mathematical developments), (iii) the comparison of several variants of MVINS filters on a real dataset showing the advantages of the invariant filter.

Furthermore, we prove consistency properties from the MSCKF equations directly. In contrast, all previous works we are aware of, transpose such theoretical results from the associated EKF-SLAM filter.

II. RELATED WORK

It has been known for many years that consistency issues can arise from linearization errors in the EKF when using it in a Simultaneous Localization and Mapping (SLAM) context. The authors of [8] demonstrated that this stems in part from the fact that some state-variables are used in several measurements equations with different linearization points. In contrast, full batch optimization of the underlying cost function does not suffer from these sources of spurious observability. However, batch methods are computationally intensive and even if incremental solvers exist [9, 10], truly real-time implementations marginalize past poses and face the same consistency issues [11]. An often used workaround is to freeze the linearization point of all variables already involved in marginalization [12]. This idea was applied to the MSCKF in [13] and to a batch approach in [11]. Yet the potential negative side effects of this practice are unclear.

Another solution is to alter artificially the transition and measurement matrices of a filter in order to enforce the non-observable space of linearized model [14]. This method is referred as Observability Constrained EKF (OC-EKF) in the literature and was applied to MSCKF with

\textsuperscript{1} D. Caruso and D. Vissière are with Sysnav
\textsuperscript{2} A. Eudes, M. Sanfourche, G. Le Besnerais are with ONERA
success in [15]. This approach is however not theoretically strongly founded.

The influence of parametrization of the error-state on the consistency property of EKF has been the subject of research for a long time [16–18]. However, the most promising works regarding this idea arose from the theory of invariance of estimators [19, 20] applied to the EKF in [21] and later to SLAM in [6]. In the latter work, the authors exploit the symmetries of the problem to design the error-state, and synthesize a consistent EKF-SLAM (EKF-SLAM). This “invariant” parametrization ideas disseminated quickly and were used in various contexts such as in [7, 22]. In particular, [23] is very close to our approach, while targeting a totally different application. Very valuable information about the mathematics behind these development can be found in [24, 25].

III. Problem statement

A. Kalman filtering with Non-linear Error

We use a very general formulation of the Kalman filter as in [24, 26], in which uncertainty is represented through the covariance matrix \(\Sigma_e\) of a non-linear error vector \(e\). The latter is defined through an abstract retraction operator \(\varrho\):\
\[ X = \tilde{X} \oplus e, \quad e \propto \mathcal{N}(0, \Sigma_e) \] (1)
where \(X\) is the true state value, \(\tilde{X}\) is the estimated one and \(\mathcal{N}\) the normal distribution. Error’s selection is merely a design choice; it defines the space where the uncertainty of the filter is approximated as a Gaussian. It also governs the linearization process of the filter. Therefore it has a major impact on the filter performance.

Loosely speaking, this error operator must verify expected properties for an error such as \(X_0 \oplus 0 = X_0\) and have a reciprocal operator \(\circ\) so that \(e = X \circ \tilde{X}\) around zero. To use it in an EKF, it must also be continuous and differentiable at least in the vicinity of zero.

Let us consider the following generic discrete dynamic model:

\[
\begin{align*}
\text{(propagation)} & \quad X_{k+1} = f(X_k, u_k, \eta_k), \\
\text{(measurement)} & \quad y = h(X_k) + \nu_k
\end{align*}
\] (2)
with \(\eta_k \propto \mathcal{N}(0, \Sigma_\eta)\) (respectively \(\nu_k \propto \mathcal{N}(0, \Sigma_c)\)) the Gaussian noise term of the propagation (respectively measurement) equation.

With this model, the Kalman propagation step writes

\[
\begin{align*}
\dot{X}_{k+1|k} &= f(\hat{X}_k, \hat{u}_k, 0) \\
\Sigma_{e_{k+1|k}} &= \Phi_k \Sigma_{e_k} \Phi_k^T + G_k \Sigma_u G_k^T + C_k \Sigma_\eta C_k^T,
\end{align*}
\] (3)
(4)
where \(\hat{u}_k \propto \mathcal{N}(\mu_k, \Sigma_u)\) is a corrupted measurement of the input \(u_k\). Matrices \(\Phi_k, G_k, C_k\) are respectively the Jacobian matrices of the process function \(f\) with respect to the state, the input, and the stochastic input of the model.

Denoting \(e_0 : e, u, \eta \mapsto f(\tilde{X}_k \oplus e, u, \eta) \oplus f(\hat{X}_k, \hat{u}_k, 0)\), these matrices are formally defined by:

\[
\begin{align*}
\Phi_k &= \frac{\partial e_k}{\partial e} \bigg|_{0, \eta_k, 0}, \\
G_k &= \frac{\partial e_k}{\partial u} \bigg|_{0, \eta_k, 0}, \\
C_k &= \frac{\partial e_k}{\partial \eta} \bigg|_{0, \eta_k, 0}
\end{align*}
\] (5)

The update step with measurement \(\hat{y}_{k+1}\) writes

\[
\begin{align*}
\tilde{X}_{k+1} &= \tilde{X}_k \oplus \left( K_{k+1} \left( \tilde{y}_{k+1} - h(\tilde{X}_{k+1|k}, 0) \right) \right) \\
\Sigma_{e_{k+1|k}} &= (I - K_{k+1} H_{k+1} \Sigma_{e_{k+1|k}})
\end{align*}
\] (6)
(7)
where the linearized measurement matrix \(H_{k+1}\) is

\[
H_{k+1} = \frac{\partial}{\partial e} \left( h(\tilde{X}_{k+1|k}, e) \right) \bigg|_{e=0}
\] (8)
and Kalman gain \(K_{k+1}\)

\[
K_{k+1} = \Sigma_{e_{k+1|k}} H_{k+1}^T \left( H_{k+1} \Sigma_{e_{k+1|k}} H_{k+1} + \Sigma_c \right)^{-1}
\] (9)

We start from the continuous model of MI-DR:

\[
\begin{align*}
\dot{\tilde{r}}^w &= \tilde{r}^w \omega^b_x, \\
\dot{\nu}^w &= \tilde{r}^w a^b + g^w; \\
\dot{p}^w &= \nu^w, \\
\dot{B}^w &= \nabla B^b \nu^w T \nu^w.
\end{align*}
\] (10)
(11)
(12)

The magnetic equation (12) is specific to MI-DR technique. The gradient of magnetic field \(\nabla B^b\) is measured from a network of magnetometer and renders the speed in body frame observable provided it is non-singular. In environments where compass capability is strongly altered by magnetic perturbations, such as indoor, this equation allows to efficiently correct accelerometers integration.

In [3] it is shown how to integrate this model to obtain the discrete dynamic model \(f\):

\[
\begin{align*}
\tilde{r}^w_{k+1} &= \tilde{r}^w_k + \Delta \tilde{R}_k, \\
\nu^w_{k+1} &= \nu^w_k + g^w \Delta t_k + \tilde{R}^w_k \tilde{\Delta} \nu_k, \\
p^w_{k+1} &= p^w_k + \tilde{v}^w_k \Delta t_k + \frac{1}{2} g^w \Delta t_k \Delta t_k^T + \tilde{R}^w_k \tilde{\Delta} \tilde{p}_k, \\
B^w_{k+1} &= B^w_k + \tilde{R}_k \tilde{\Delta} \tilde{B} \nu_k \nu_k^T \tilde{R}_k + \tilde{R}_k \tilde{\Delta} \tilde{B}_g \tilde{R}_g ^T \tilde{R}_k \tilde{\Delta} \tilde{B}_n \nu_k
\end{align*}
\] (13)
(14)
(15)
(16)

Where we introduced abruptly the notations \(\tilde{\Delta} \tilde{R}_k \in \text{SO}(3), \tilde{\Delta} \nu_k \in \mathbb{R}^3, \tilde{\Delta} \tilde{p}_k \in \mathbb{R}^3\) and \(\tilde{\Delta} \tilde{B} \nu_k \in \mathbb{R}^3, \quad \tilde{\Delta} \tilde{B}_g \tilde{R}_g \in \mathbb{R}^3, \quad \tilde{\Delta} \tilde{B}_n \tilde{R}_n \in \mathbb{R}^3\). They stand for integrated quantities that can
be computed from received measurements. Their exact expressions depend on a choice of integration method. They do not matter here (see [3] for more details).

Within the MSCKF technique, the state of the filter is augmented by a few past states, we define it:

$$X_k = (X_k^{sc}, X_k^m)$$

where \(X_k^m = (\hat{x}_k^m, p_k^m, y_k^m, B_k^w)\) is the current state and \(X_k^{sc} = (\hat{x}_k^{w}, p_k^{w}, y_k^{w}, \cdots, \hat{x}_{k-1}^{w}, p_{k-1}^{w})\) is compound of \(nc\) "stochastic clones" [4] states (here past camera poses still in the sliding window). In [3], the error-state was simply defined with a substitution between real state and estimated state, except for its rotational part where the distance \(\log_{\text{SO}(3)}(R R^T)\) is used.

The MI-MSCKF filter uses two measurements. On one hand magnetic measurement is a direct measurement of the field state, in body frame: \(h_{\text{magn}}(X_k) = R^w T B_k^w\).

On the other hand, a visual measurement is built when a corner feature's track ends in the image stream. For a given track, the measurement equation collects the reprojection errors computed on all images taken at stochastic cloned instants:

$$h_{\text{feat}}(\hat{X}, t) = \left[ \pi \left( \hat{X}_k^w (1 - p_k^w) \right) \cdots \pi \left( \hat{X}_{k+1}^w (1 - p_k^w) \right) \right]^T$$

where \(\pi\) is the projection function of the camera. The feature measurement is linearized according to:

$$h_{\text{feat}}(\hat{X} \in \mathcal{O}, t^* + \delta t) \simeq h_{\text{feat}}(\hat{X}, t^*) + F e + E \delta l$$

where \(F\) (resp. \(E\)) is the Jacobian of \(h_{\text{feat}}\) with respect to the stochastic cloned part of the state (resp. to the landmark position parameters \(l\)).\(^\text{1}\) In this expression, the linearization point \(t^*\) comes from triangulation, assuming known past poses. The measurement matrix \(H_{\text{feat}}\) is computed by projecting this equation over the nullspace of \(E\) with a QR decomposition:

$$H_{\text{feat}} = O_0^T F \quad \text{with} \quad E = [O_1, O_0] \begin{bmatrix} R \ 0 \end{bmatrix},$$

with \([O_1, O_0] \in \mathcal{O}\) and \(R\) an upper triangular matrix.

The projection steps (20) eliminates the need to augment the filter state with landmark positions. This is the big improvement of MSCKF-like algorithm compared to traditional EKF-SLAM filter: it saves both computation and memory requirements.

**Note:** In this section and hereafter, we choose to write all formulas without biases, albeit accelerometer and gyroimeters biases are estimated by the filter in all experiments — as commonly done in VIO literature. This simplify derivations, as bias estimation does not change the property we prove later on regarding the invariance to stochastic transform as noted in [7].

\(^\text{1}\)The landmark parametrization can be chosen indifferently: we took as example 3D position of landmark in world frame but could be also 3D position in the coordinate frame of the first camera, inverse depth parametrization on first ray, etc.
Definition 1. (Stochastic transform of an EKF state) We call a stochastic transform of an EKF state at time \( k \) the following transformation:
\[
\tilde{X}_k \mapsto T_\theta(\tilde{X}_k, 0), \quad \Sigma_{ek} \mapsto M \Sigma_{ek} M^T + N \Sigma N^T, \tag{21}
\]
with \( M = \frac{\partial}{\partial \theta} \left( T_\theta(\tilde{X} \boxplus e, 0) \boxplus T_\theta(\tilde{X}, 0) \right) \bigg|_{e=0} \) and \( N = \frac{\partial}{\partial \eta} \left( T_\theta(\tilde{X}, \eta) \boxplus T_\theta(\tilde{X}, 0) \right) \bigg|_{\eta=0} \) \)

By extension we will call \( T_\theta \) the stochastic transform (function).

Definition 2. (Invariance of an EKF output to unobservable stochastic transform) The EKF output is said to be invariant to an unobservable stochastic transformation if both following statements are true:

1) For all \( \eta \in \mathbb{R}^N \), the stochastic transform \( T_\theta : (X, \mathbb{R}^N) \rightarrow X \) describes a unobservable transformation of the model/output on which the EKF is based on. I.e, if at time \( i \) we have \( \tilde{X}^a_i = T_\theta(\tilde{X}^b_i, \eta) \) then \( \forall n > i, h(\tilde{X}^a_n) = h(\tilde{X}^b_n) \) (noting with indices \( n \) the quantities obtained by applying repeatedly the discrete transition function)

2) For any two estimate and covariance of the EKF at time \( i \), say \( (\tilde{X}^a_i, \Sigma_{ek}^a) \) and \( (\tilde{X}^b_i, \Sigma_{ek}^b) \), so that \( b \)-quantities are computed from the stochastic transformation of \( a \)-quantities, we have equality of output sequence of the two instances of the filter based on respectively \( a \)- and \( b \)-quantities as initialization values: \( \forall n > i, h(\tilde{X}^a_n) = h(\tilde{X}^b_n) \)

Intuitively, this last definition states that, whatever are the unobservable quantities values initialized to, and whatever are the initial uncertainty along the unobservable direction in the initial covariance, the innovation sequence of the filter should not change: one property we would expect from a consistent filter. For MVINS, respecting Definition 2 means that the mean estimate sequence should not be modified by changing solely the initial heading uncertainty. This was proved wrong for the MI-MSCKF in previous section.

C. Two stochastic transforms of interest

This section exposes two properties that will be used in Section V-B in order to prove the invariance of a new filter to all unobservable stochastic transformations of its model. Sufficient conditions were introduced in [7] to prove by simple computation the invariance of an EKF for two particular types of stochastic transform functions: purely deterministic transform (verifying \( \forall \eta, X, T_\theta(X, \eta) = T_\theta(X, 0) \) and stochastic identity transform (verifying \( \forall X, T_\theta(X, 0) = X \)).

1) Invariance of an EKF to a deterministic transform:

**Property 1.** Let \( T_\theta \) denotes a stochastic transform function. The output of an EKF is invariant under the deterministic part of this transform, \( X, \eta \mapsto T_\theta(X, 0) \), if:

(i) the process function \( f \) commutes with \( T_\theta(\cdot, 0) \) and, (ii) there exists a constant invertible matrix \( W_\theta \) such that:

\[
\forall e, \tilde{X}, \quad T_\theta(\tilde{X} \boxplus e, 0) = T_\theta(\tilde{X}, 0) \boxplus W_\theta e \tag{24}
\]

Proof insight: we consider an EKF built on the model with a choice of error verifying (24) and we assume that two such filters are running concurrently. The first starts from the initial estimate \( (\tilde{X}_i, \Sigma_{X_i}) \) at time \( i \).

The second starts from the initial estimate \( (\tilde{Y}_i, \Sigma_{Y_i} = (T_\theta(\tilde{X}_i, 0), W_\theta \Sigma_{X_i} W_\theta^T) \), a deterministic transform of the first one. It is possible to show by brute force calculus that after one propagation and one update, the two filter estimates and covariances are still related one to the other with the same unobservable deterministic transform. Conclusion can be drawn by induction. The condition (i) is necessary to the proof ([27, p.152]).

2) Invariance of an EKF to a family of stochastic identity transform:

**Property 2.** Let \( T_{I_{\theta}} \) be a stochastic transform function fulfilling stochastic identity transform properties. The output of an EKF is invariant under \( T_{I_{\theta}} \) if:

\[
\forall n \text{ and } i \geq 0, \quad H_{n+i+1} \Phi_n^i \Phi_{n+i-1} \cdots \Phi_1 N_i = 0 \tag{25}
\]

Proof insight: Let us consider an EKF built on the model with an error verifying (25) and suppose two instances of it are started. The first one from estimate \( (\tilde{X}_i, \Sigma_{X_i}) \) at time \( i \). The second from estimate \( (\tilde{Y}_i, \Sigma_{Y_i} = N_i \Sigma N_i^T) \), an unobservable stochastic transform of the first one. By calling the subsequent estimate of the second filter \( \tilde{Y}_{n+i} \) and \( \Sigma_{Y_n} \), we can show by recursion that:

\[
\forall n \geq i, \quad \tilde{Y}_n = \tilde{X}_n \quad \text{and} \quad \Sigma_{Y_n} = \Sigma_{X_n} + \Phi_n \Phi_{n-1} \cdots \Phi_1 N_i \Sigma N_i^T \Phi_i^T \cdots \Phi_{n-1}^T \Phi_n^T \tag{26}
\]

The first equality induces that the filter output is invariant to identity stochastic transform.

V. AN INVARiANt PARAMETRIZATION

A. Lie Group embedding of the MI-DR state

We borrow and adapt to our problem the invariant parametrization of IMU states originally presented in [21]. Despite the fact that the miraculous log-linear property of [21] does not hold for MVINS discrete model \(^3\), we show in this paper that this invariant parameterization gives the filter a lower property of invariance to stochastic transformation.

\(^3\)this stems from magnetic equations, even when disregarding biases; a simple calculus using [25, Theorem 2] proves it.
We base a new error definition on the following matrix Lie group embedding, named $SE(3)$ by the authors of [21], of the MI-DR state (stochastic clones part of the state is treated hereafter):

$$X^m = \begin{bmatrix} R^w & v^w & p^w \nabla B^w \\ 0_{3,1} & I_{3,3} \end{bmatrix}$$  \hspace{1cm} (27)

$$(X^m)^{-1} = \begin{bmatrix} R^w & -R^wv^w & -R^wp^w - R^wT B^w \\ 0_{3,1} & I_{3,3} \end{bmatrix}$$  \hspace{1cm} (28)

$R^w \in \text{SO}(3), v^w, p^w, B^w \in \mathbb{R}^3$,

and focus on the “right-invariant” error that writes:

$$\epsilon = X^m (X^m)^{-1}$$  \hspace{1cm} (29)

$$= \begin{bmatrix} R^wR^w & R^wv^w - R^wR^wv^w & R^wp^w - R^wR^wp^w \nabla B^w - R^wR^wB^w & 0_{3,1} & I_{3,3} \end{bmatrix}$$

This error can be associated to a vector error through the vectorized matrix Lie group logarithm $\log_{SE(3)}(\epsilon)$. Its Lie algebra $se_3(3)$ is the set of matrices of the following form:

$$e^m \land = \begin{bmatrix} [e_0]_X & e_v & e_p & e_B \\ 0_{3,1} & 0_{3,1} & 0_{3,1} & 0_{3,1} \end{bmatrix}, \quad e^m \land \in se_3(3)$$  \hspace{1cm} (30)

with $e^m = \begin{bmatrix} e^0_y \\ e^T v \\ e^T p \\ e^T B \end{bmatrix} \in \mathbb{R}^{12}$;

For concision, we will write elements dropping the trivial parts of the matrix and write the shortcuts $e^a$ for $\exp_{SO(3)}(e_R)$, $\exp(e^m \land)$ for $\exp_{SE_3}(e^m \land)$. The exponential matrix operator on this matrix Lie group associates an element of its Lie algebra to an element of the group. One has in reduced notations:

$$\exp(e^m \land) = \begin{bmatrix} J_{R}(e_R) e_v \\ J_{R}(-e_R) e_p \\ J_{R}(-e_R) e_B \end{bmatrix}$$  \hspace{1cm} (31)

where $J_{R} : \mathbb{R}^3 \rightarrow \mathbb{R}^{3 \times 3}$ is the right jacobian of $SO(3)$ [28]:

$$J_{R}(\theta) = I_3 - \frac{1 - \cos \|\theta\|}{\|\theta\|^2} [\theta]_X + \frac{\|\theta\| - \sin \|\theta\|}{\|\theta\|^3} [\theta]_X^2$$  \hspace{1cm} (32)

We use this exponential to define the error by the following $\boxplus$ and $\boxtimes$ operators:

$$X^m_k = X^m_k \boxplus e^m_k = \exp(e^m \land_k) X^m_k$$  \hspace{1cm} (33)

$$e^m_k = X^m \boxtimes X^m_k = \log_{SE_3}(X^m_k (X^m)^{-1})$$  \hspace{1cm} (34)

For the stochastically cloned part of the state, we use a left multiplication by the natural SE(3) exponential of the error as retraction operator for each stochastic cloned pose:

$$\exp_{SE(3)}\left(\begin{bmatrix} e^0_R & J_{R}(-e_R)e^0_p \\ 0 & 1 \end{bmatrix} \right) = \begin{bmatrix} e^{0_R} & J_{R}(-e_R)e^0_p \\ 0 & 1 \end{bmatrix}$$  \hspace{1cm} (35)

The stochastic clone errors are concatenated together with $e^m$ and respective retraction operators are used to define an error from which we build a new MVINS filter denoted RI-MI-MSCKF, where RI stand for “right-invariant”.

Hereafter, we name $M$ the Lie group structure on the state of the filter as the following direct product: $M = SE(3) \times \ldots \times SE(3) \times SE_3(3)$.

B. Proof of the invariance of this parametrization

In this section we prove the invariance to stochastic unobservable transform of the RI-MI-MSCKF with help from properties defined in Section IV-C.

1) Stochastic unobservable transform for MVINS model

In order to work with the observability properties of our model, we define formally the set of unobservable stochastic transform corresponding to composition of rotation around the gravity vector and global translation of world coordinates.

Definition 3. (Unobservable stochastic transform for MI-MSCKF model) We parametrize the family of unobservable stochastic transforms for the model in the following way:

$$\mathcal{T}(X, \eta, \theta) \triangleq \begin{bmatrix} e^{(n_1 + \eta_1) \theta} & e^{(n_2 + \eta_2) \theta} & \cdots \\ e^{(n_1 + \eta_1 + \theta_1) \theta} & e^{(n_2 + \eta_2 + \theta_2) \theta} & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix}$$  \hspace{1cm} (36)

with $X \in M, \eta \in \mathbb{R}^4, \theta \in \mathbb{R}^4$.

Note that, we now put $\theta$ as a proper $\mathcal{T}$ argument function as we can parametrize stochastic transform of interests through $\mathbb{R}^4$. We can decompose each element of the family into one stochastic identity transform $\mathcal{T}(X, \eta, 0)$ and one deterministic transform $\mathcal{T}(X, \theta, 0)$ thanks to the following equality that can be easily verified for MVINS model:

$$\mathcal{T}(X, \eta, \theta) = \mathcal{T}\left(\mathcal{T}(X, 0, \theta), \eta, 0\right) = \mathcal{T}\left(\mathcal{T}(X, 0, \eta), \theta\right)$$  \hspace{1cm} (37)

So, to prove that the filter is invariant to all unobservable stochastic transforms, we first prove that it is invariant to all element’s deterministic part in the family: $X, \eta \mapsto \mathcal{T}(X, 0, \theta)$ then prove that it is invariant to stochastic identity transform $X, \eta \mapsto \mathcal{T}(X, \eta, 0)$. 

5
2) Property 1 verification: The condition (24) is verified for our parametrization with:

$$W_D = \begin{bmatrix} 0 & 0 & 0 & 0 \\ \vdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 \end{bmatrix}, \quad (41)$$

with $W_D^{sc} = \begin{bmatrix} e^{\theta_1 g} & 0 & 0 & 0 \\ [\theta_2:4] \times e^{\theta_1 g} & e^{\theta_1 g} \\ 0 & e^{\theta_1 g} & 0 & 0 \\ 0 & 0 & e^{\theta_1 g} & 0 \end{bmatrix}$, and $W_D^m = \begin{bmatrix} e^{\theta_1 g} & 0 & 0 & 0 \\ [\theta_2:4] \times e^{\theta_1 g} & e^{\theta_1 g} & 0 & 0 \\ 0 & e^{\theta_1 g} & 0 & 0 \\ 0 & 0 & e^{\theta_1 g} & 0 \end{bmatrix}$

which proves the invariance to $T(\cdot, 0, \theta)$. The proof consists mainly in calculus with SO(3) properties and is not presented here: it can be found in [27].

3) Property 2 verification: Note that, in the Property 2, the measurement $Hs$ and transition $\Phi$ matrices are those used effectively by the filter, i.e. linearized at the estimated values, different of the real unknown values. In contrast with [7], we work here directly on the MSCKF state for proving the property of invariance to unobservable stochastic transform, which is a more straightforward but unusual way to tackle the problem.

The outline of subsequent calculus is the following: first, we will compute $N_i$, as in Definition 1. Secondly, we will compute the structure of the transition matrix $\Phi$. We will be able to show that $N_i$ is left unchanged by left multiplication with transition matrix $\Phi$. We will show that for both magnetic and visual measurement update, the linearized measurement matrices $H$ involved verifies Property 2. We will then conclude.

a) Computation of $N_i$: Taking into account the stochastic cloned part of the state. The computation of $N_i$ following Definition 1 leads to:

$$N_i = \begin{bmatrix} \cdot & g^T & 0_3 & \cdot & g^T & 0_3 & 0_3 & 0_3 \\ \cdot & 0_3 & I_3 & \cdot & 0_3 & 0_3 & I_3 & 0_3 \end{bmatrix}^T \quad (42)$$

Remarkably, this matrix does not depend on the state estimate, thanks to the choice of the parametrization.

b) Structure of transition matrix $\Phi$: We only need some part of the structure of $\Phi_k$ to prove our property.

In the MSCKF algorithm, the prediction step can also involve stochastic cloning: we write $\Phi$ in the following form:

$$\Phi_k = \begin{bmatrix} \Phi_k^{Sc1} & \Phi_k^{Sc2} \\ 0 & \Phi_k^{m} \end{bmatrix} \quad \text{with} \quad \left[ \Phi_k^{Sc1} \Phi_k^{Sc2} \right] = \begin{bmatrix} I_{3,3} & \ast & 0_{3,3} & \ast \\ \Delta t_k [g] \times & \ast & 0_{3,3} & \ast \\ \Delta t_k^2 [g] \times & \ast & I_{3,3} & \ast \\ R_k \Delta B_{k,k+1} [g] \times & \ast & 0_{3,3} & \ast \end{bmatrix} \quad (44)$$

With this structure, we verify easily that $\Phi_{k+1}N_k = N_k$ and that, by recursion, we have:

$$\forall n \text{ and } i \geq 0, \quad \Phi_{n+i} \Phi_{n+i-1} \cdots \Phi_1 N_{i} = N_i \quad (45)$$

This is very handy to prove condition (25) as it is now sufficient to show that $HN_i = 0$. We now prove it both for magnetic and visual measurement.

c) Magnetic update: The magnetic update is related directly to the current states:

$$h_{magn}(X_k) = r_k^T B_k$$

Computing the first order approximation yields:

$$h_{magn}(X_k \oplus \eta) = r_k^T e^{-\eta} (e^{-\eta} B_k + J_r (-e_k) e B)$$

$$= h_{magn}(X_k) + r_k^T e B + o(\|\eta\|)$$

Thus the measurement matrix to use is:

$$H_{magn} = \begin{bmatrix} 0_{3,6nc} & 0_{3,9} & r_k^T & 0_{3,6} \end{bmatrix}$$

And we have by simple computation: $H_{magn} N_i = 0$.

This proves the condition (25) if we had only the magnetic measurement equation. At that point we have thus exhibited a pure magneto-inertial filter that fulfills invariance to stochastic transform. Such a filter was not presented before as far as we know.

d) Visual update: For visual measurements, showing the relation by a direct computation is more cumbersome because of the way the landmark position parameters are eliminated from the measurement function in the MSCKF. Instead, we are going to leverage the invariance of the reprojection function $h_{\text{feat}}$ without having to compute $H_{\text{feat}}$ explicitly to show that $H_{\text{feat}} N_i = 0$.

We assume here that landmarks are parameterized by their position $l \in \mathbb{R}^3$ in world frame. We can write the following equality:

$$\forall \hat{X} \in M, \eta \in \mathbb{R}^{4}, l \in \mathbb{R}^{3}, \quad h_{\text{feat}}(\hat{X}, l) = h_{\text{feat}}(T(\hat{X}, \eta, 0), e^{\eta \hat{g}} 1 + \eta 2:4) \quad (46)$$

which merely expresses frame invariance of the calibrated monocular reconstruction problem. Differentiation of the equality with respect to $\eta$ gives:

$$\begin{aligned} \frac{\partial}{\partial \eta} h_{\text{feat}}(\hat{X}, l) & = h_{\text{feat}}(T(\hat{X}, \eta, 0), e^{\eta \hat{g}} 1 + \eta 2:4) \quad (47) \\
FN_i = E[\frac{\partial}{\partial \eta} h_{\text{feat}}(l, \hat{g}, l_3)] \quad (48) 
\end{aligned}$$

Starting from (20) and substituting previous equation one has:

$$H_{\text{feat}} N_i \overset{\text{(20)}}{=} O_0^T FN_i \overset{\text{(48)}}{=} O_0^T E[\frac{\partial}{\partial \eta} h_{\text{feat}}(l, \hat{g}, l_3)] \quad (49)$$
Fig. 2: heading uncertainty propagated by the invariant filter; bottom: the x position estimated by the filters. Both are with five different initial heading uncertainties. The five curves on bottom figure cannot be distinguished. With the new parametrization, the initial heading uncertainty does not influence the position estimate of the filter, and the estimation of heading uncertainty stays constant as expected. Please compare to Fig. 1 depicting the behavior of the filter of [3].

And by definition (20) of $O_0$: $O_0^T r = 0$ and finally the condition (25) $H_{feat} N_f = 0$ holds$^4$.

We thus have proven that the output of RI-MI-MSCKF for the MVINS system is invariant under $T(\cdot, \cdot, 0)$.

Combined with the invariance to deterministic transform proved in (41) and using the equality noticed in (40), we prove that the RI-MI-MSCKF is invariant to any stochastic unobservable transform of the MVINS system.

Note: OC-EKF method can be applied to the MVINS problem [3]. The resulting estimator also verifies Definition 2. However, such approach is less theoretically satisfying and it is not clear that it does not introduce errors, as it is quite arbitrarily build from a Frobenius norm minimization. We name this estimator OC-MI-MSCKF in the next section.

VI. EXPERIMENT AND COMPARISON ON REAL DATA

We implemented the two alternate versions, RI-MI-MSCKF and OC-MI-MSCKF of the MI-MSCKF and conducted a comparative study on real datasets described in [3]. In these implementations, we parameterize landmarks with an inverse depth in the first ray, and use Harris corner and KLT for features detection and tracking. Visual outliers are rejected with a two views gyro-aided RANSAC and a $\chi^2$ gating test. Stochastic cloning occurs at least at 10Hz.

A. Improved behaviour with inaccurate heading

First, we verify on the data of Section IV that the RI-MI-MSCKF heading uncertainty and position outputs are in line with the proven invariance results (compare Fig. 2 with Fig. 1).

For further analysis, we run the three filters equally initialized with the true heading and a large heading covariance, while taking care to use the same parameters and measurements (we bypass non deterministic outlier rejection for this experiment). Thus, we expect the three

$^4$If we were to use an inverse depth in first ray parametrization of features, the condition is also true, and can be demonstrated similarly. $\forall x, \eta, l, h(x, l) = h(T(x, \eta, 0), d)$ so that by differentiating with respect to $\eta$ one directly has $0 = FN$,.

which stay smooth the entire trajectory long. Secondly, of the heading. This specific case would deserve further in the case of delayed or/and temporary observability. We believe that the use of the Lie Group could be beneficial than the observability constrained version. Also, we the proposed invariant of $\text{mi-msckf}$ estimation over long trajectories. According to our tests we display only the best and worst trajectories of ten runs.

pattern to improve the accuracy of estimating the final location. We observe two interesting facts from the final part of the trajectories. First, the MI-MSCKF trajectory is more chaotic than RI-MI-MSCKF and OC-MI-MSCKF which stay smooth the entire trajectory long. Secondly, Fig. 4 shows statistics of the Normalized Estimation Errors measured at the end of trajectory: a low value is a proof of consistency, it reveals that RI-MI-MSCKF is slightly more consistent than OC-MI-MSCKF. We also unexpectedly observe that the final locations of MI-MSCKF are more dispersed than the two others, MI-MSCKF seems to be more sensitive to the input visual features than the others. An explanation could be that consistency improves in return the $\chi^2$ outlier gating test.

VII. Conclusion

We derived an original invariant parametrization of the MI-MSCKF and demonstrated its invariance to unobservable stochastic transform, a property naturally expected from an EKF when filtering with partially unobservable state. We have shown on real data that the proposed parametrization gives to the filter the ability to handle correctly the case of inaccurate heading initialization, as well as it significantly improves the smoothness of the estimation over long trajectories. According to our tests the proposed invariant of MI-MSCKF is more consistent than the observability constrained version. Also, we believe that the use of the Lie Group could be beneficial in the case of delayed or/and temporary observability of the heading. This specific case would deserve further analysis though.
